I. INTRODUCTION

Until the discovery of the protocol of entanglement-based quantum cryptography [1], Bell’s theorem was relevant only in discussions concerning foundations of quantum mechanics. It established means to evaluate the most reasonable class of hidden variable theories, i.e., local and realistic theories. Once the theorem proved useful in quantum cryptography and of hidden variable theories, i.e., local and realistic theories.

It is very easy to notice that the problem of existence of a local hidden variable model for the given set of quantum probabilities is a form of linear programming problem (see Sec. II). Thanks to such an approach it was possible to show for example that nonclassicality of two-qubit correlations is higher than for qubits, and that it increases with the dimension [9].

Below we present how linear programming can be harnessed to study nonclassicality of quantum correlations. This approach was put in the form of a computer code: STEAM–ROLLER. We will present the numerical results in Secs. III and IV. Here we particularly aimed at multisetting scenarios for multiqubit states which are known to possess interesting kinds of nonclassical behavior. Most of our results cover regions for which the full set of Bell’s inequalities is unknown. Even the results for two settings per observer cover a different territory: they are produced for the full set of probabilities for the given N-qubit problem. In the case of the WWWZB inequalities [6,7,10] only highest order correlation functions [11] are taken into account. These do not reflect interference effects that may occur between subsets of particles. Thus the WWWZB set, despite being complete for highest order correlation functions (in the case of a two setting choice per observer), is not complete for the full description of quantum phenomena. This full set of probabilities for the given problem gives full knowledge about an experiment and therefore contains all available information.

II. LINEAR PROGRAMMING

In the most general Bell’s experiment, N observers perform measurements on a given state \( \rho_N \). Each observer can choose between \( m_i \) arbitrary dichotomic observables (i = 1, …, N). Their measurement results will exhibit correlations not describable by classical statistics (i.e., by classical realistic models). For brevity let us consider a case with two observers (Alice and Bob) and two measurement settings per side. In this case the local realistic models are equivalent to the existence of a joint probability distribution \( p_n(a_1,a_2,b_1,b_2) \), where \( a_i = \pm 1 \) denotes the result of the measurement of Alice’s \( i \)-th observable (Bob’s results are denoted by \( b_i = \pm 1 \)).

Quantum predictions for the probabilities are the marginal sums of the above joint probability distribution \( p_n \):

\[
\begin{align*}
P_{QM}(r_a,r_b|A_1,B_1) &= \sum_{a_2,b_2 = \pm 1} p_n(a_1,a_2,r_b,b_2), \\
P_{QM}(r_a,r_b|A_1,B_2) &= \sum_{a_2,b_1 = \pm 1} p_n(a_1,a_2,b_1,r_b), \\
P_{QM}(r_a,r_b|A_2,B_1) &= \sum_{a_1,b_2 = \pm 1} p_n(a_1,r_a,b_2,\pm 1), \\
P_{QM}(r_a,r_b|A_2,B_2) &= \sum_{a_1,b_1 = \pm 1} p_n(a_1,r_a,b_1,r_b),
\end{align*}
\]

DOI: 10.1103/PhysRevA.82.012118 PACS number(s): 03.65.Ud
where $P_{QM}(r_a, r_b|A_i, B_k)$ denotes the probability of obtaining the result $r_a$ by Alice and $r_b$ by Bob, when they measure the observables $A_i$ and $B_k$, respectively. It has been shown that for some entangled states, no local realistic probability distribution $p_{\rho}(a_1, a_2, b_1, b_2)$ exists, which could satisfy the set of equalities (1). Therefore, no local realistic model can reproduce the predictions of quantum mechanics for these entangled states. This statement is known as Bell’s theorem [12].

This is one of the ways one can express Bell’s theorem. The more frequent approach is to find certain (Bell) inequalities which are satisfied by local realistic models, but violated by some quantum predictions. More importantly, there are many statements on the “strength” of a violation of such inequalities which use such terms as “amount of violation” or “factor of violation.” However, such measures cannot be used for direct comparison between different Bell inequalities or with a different method, such as the one used in our paper. Thus, following [9], we shall use a “violation” parameter $v_{crit}$ which seems to be much more objective: we shall seek the amount of random (“white”) noise admixture that is required to completely hide the nonclassical character of the original correlations for the given state.

If we mix some amount of white noise to the two-qubit state $\rho$, we obtain a state described by the following density operator:

$$\rho(v) = v\rho + \frac{1-v}{2^n}I \otimes I. \quad (2)$$

The quantum probability $P_{QM}^{v}(r_a, r_b|A_i, B_k)$ for the state $\rho(v)$ reads

$$P(r_a, r_b|A_i, B_k) = vP_{QM}(r_a, r_b|A_i, B_k) + \frac{1}{2^n}(1-v). \quad (3)$$

The parameter $v$ is the visibility of the state, and obviously $(1-v)$ is the amount of noise admixture. For $v = 0$ the equalities (1) are obviously satisfied (white noise has a local realistic model). For $v = 1$ the equalities (1) cannot be satisfied for some entangled states $\rho$ (and for a particular choice of observables). For such states there exists the critical visibility $v_{crit}$ that for $v \leq v_{crit}$ there exists a local realistic probability distribution $p_{\rho}(a_1, a_2, b_1, b_2)$ that satisfies the set of equalities (1).

A set of 16 probabilities $P_{QM}(r_a, r_b|A_i, B_k)$ corresponds to a single point in a 16-dimensional space. Those sets which can be described using local realistic models form a convex geometric figure called a Bell-Pitovsky polytope in this 16-dimensional space. The facets of the polytope are equivalent to tight Bell inequalities. For $v = v_{crit}$ the local realistic probability distributions $p_{\rho}(a_1, a_2, b_1, b_2)$ lead to a set of probabilities $P_{QM}(r_a, r_b|A_i, B_k)$ which form the coordinates of a geometric point which lies in a facet of the polytope (i.e., they saturate a Bell inequality). It has to be noted, however, that our numerical method does not lead to uncovering particular Bell inequalities which are violated by an investigated state. We think that the power of the method lies in the fact that one does not need any knowledge at all of the forms of Bell inequalities when analyzing nonclassicality of quantum-entangled states. Seeking violated Bell inequalities is highly inefficient, since even in the simplest cases one ends up with an exploding number of Bell inequalities, the bulk of them trivial. We skip this cumbersome step entirely, see the following paragraphs.

As mentioned, critical visibility $v_{crit}$ depends on the particular set of observables Alice and Bob choose from. We can parametrize any dichotomic $v_{crit}$ $v$ depends on the particular set of observables Alice and Bob choose from. We can parametrize any dichotomic $v$ can be calculated by means of linear programming. The quantum probability can be calculated as:

$$P_{QM}(r_a, r_b|A_i, B_k) = \text{Tr}(\rho_{r_a,A}\otimes \rho_{r_b,B}).$$

Hence we can define the critical visibility function of the angles

$$v_{crit}(\theta^A, \phi^A, \theta^B, \phi^B) \in [0, 1]. \quad (5)$$

Our task is to find, for a given state $\rho$, the minimal critical visibility. If the two observers $A$ and $B$ perform two measurements each, the probabilities (3) are then parametrized by the angles:

$$P(r_a, r_b|A_i, B_k) = P(r_a, r_b, \theta^A, \phi^A, \theta^B, \phi^B). \quad (6)$$

The critical visibility is obtained by maximization of the visibility until the set of equalities (1) can no longer be satisfied. This is done by means of linear programming. We adopt

$$p_0 \equiv p_{\rho}(-, -), \quad p_1 \equiv p_{\rho}(-, +), \quad \ldots \quad p_{n-1} \equiv p_{\rho}(+, +), \quad (7)$$

where $n = 2^{m_1 + \cdots + m_n}$, and hereby give a complete description of the linear programming problem to be solved [based on Eqs. (1) and (3)] for the case with Alice and Bob:

$$\sum_{a_1,b_1 = \pm 1} p_{\rho}(a_1, a_2, r_b, b_2) = 1 - \frac{1-v}{2^n} + vP(r_a, r_b, \theta^A_1, \phi^A_1, \theta^B_1, \phi^B_1),$$

$$\sum_{a_1, b_1 = \pm 1} p_{\rho}(a_1, a_2, b_1, r_b) = 1 - \frac{1-v}{2^n} + vP(r_a, r_b, \theta^A_1, \phi^A_1, \theta^B_2, \phi^B_2),$$

$$\sum_{a_1, b_1 = \pm 1} p_{\rho}(a_1, r_b, a_2, b_2) = 1 - \frac{1-v}{2^n} + vP(r_a, r_b, \theta^A_2, \phi^A_2, \theta^B_1, \phi^B_1),$$

$$\sum_{a_1, b_1 = \pm 1} p_{\rho}(a_1, b_1, r_b) = 1 - \frac{1-v}{2^n} + vP(r_a, r_b, \theta^A_2, \phi^A_2, \theta^B_2, \phi^B_2),$$

$$\sum_{k=0}^{n-1} p_k = 1, \quad 0 \leq v \leq 1, \quad 0 \leq p_k \leq 1, \quad (8)$$

where $z$ is the (trivial) function to be maximized.

In the general case the four expressions above evaluate to $c = 2^N m_1 \cdots m_N$ equalities (e.g., for three qubits and six measurement settings per side, there are 1728 equalities). The above is known as the canonical form of the linear programming problem. We use the revised simplex method [13] from the GNU Linear Programming Kit [14].
to solve this problem. The top constraints form a simplex in the 
\((n + 1)\)-dimensional space spanned by \(p_0, \ldots, p_{n-1}\) and \(v\). The 
algorithm traverses the vertices of the simplex until it finds the 
optimal solution. The returned solution is the global 
maximum of \(z\)—the critical visibility we seek. The minimization 
over the angles \(\phi^A, \phi^B, \phi^A, \phi^B, \phi^A, \phi^B\) is realized by the 

Please note that the complexity of the linear programming 
problem is defined by \(n\) and \(c\) values which increase exponentially 
with the number of observers \(N\) or the number of settings \(m_i\) per observer. We are, therefore, limited to the computational 
capabilities of today’s numerical machines when solving this 
problem. We used a machine with an Intel Pentium D CPU 
3.20-GHz processor for our computations. Some of the results 
in this paper took several weeks to compute. Computations of 
results for bigger problems can be anticipated to complete in 
a reasonable time when using faster machines in the future.

One might wonder about the credibility of the results 
presented in this paper. There are two aspects which raise 
doubts, namely, numerical precision and local minimum 
risk when computing the minimum of the critical visibility 
function. Please note that there is no local maximum risk when 
computing the value of the critical visibility function—the single 
plex algorithm guarantees it will always find the global 
maximum as described in [13]. As for the precision of the 
results, we will not conduct an extensive analysis but will 
plainly state that this is not an issue. For all the results which 
can be calculated analytically, STEAM-ROLLER-generated results 
are compliant on all 14 displayed significant digits. For example, 
for a two-qubit Greenberger-Horne-Zeilinger (GHZ) 
state, the analytically derived minimal critical visibility is 
\( \sqrt{2} \) and STEAM-ROLLER gives 0.70710678118655. One of the 
reasons for such outstanding precision is that the numerical 
errors do not propagate between consecutive critical visibility 
function invocations. Another is that the linear programming 
library used properly handles numerical instabilities. The local 
minimum risk when computing the critical visibility function is 
more of an issue. There is no guarantee we have reached 
the global minimum, and STEAM-ROLLER did fall into a local 
minimum from time to time. One should, therefore, treat all the 
results in this paper in the following way: it is guaranteed 
that a given state has a minimal critical visibility not greater 
than the one presented. As for the likelihood that it is also 
not smaller, we can only state that there is a good chance it is 
because STEAM-ROLLER provided us with a correct result in 99 
cases out of 100.

III. BOUNDS ON LOCAL REALISM

We applied the numerical method to different types of 
quantum states, which are often discussed in the context of 
quantum-information studies, namely,

1. the generalized GHZ state [17,18]

\[ |\text{GHZ}(\alpha)\rangle_N = \cos \alpha |\cdots0\rangle_N + \sin \alpha |\cdots1\rangle_N, \]

2. the W state [19]

\[ |W\rangle_N = \frac{1}{\sqrt{N}}(|10\cdots0\rangle_N + |010\cdots0\rangle_N + \cdots + |0\cdots1\rangle_N), \]

3. the four-qubit singlet state [7,20]

\[ |\Psi_4\rangle = \frac{1}{\sqrt{3}}(|0011\rangle + |1100\rangle) \]

\[ - \frac{1}{\sqrt{12}}(|0101\rangle + |0110\rangle + |1001\rangle + |1010\rangle), \]

4. the six-qubit singlet state [20,21]

\[ |\Psi_6\rangle = \frac{1}{\sqrt{2}}(|\text{GHZ}^-\rangle + \frac{1}{\sqrt{2}}(|W\rangle_3|W\rangle_3 - |W\rangle_3|W\rangle_3), \]

where \(|\text{GHZ}^-\rangle = \frac{1}{\sqrt{2}}(|000111\rangle - |111100\rangle), \) and \(|W\rangle_3\) is the 
spin-flipped \(|W\rangle_3\).

5. the symmetric Dicke state [22]

\[ |D_N^{(N/2)}\rangle = \binom{N}{N/2}^{-1/2} \sum_{\text{permutations}} |0\cdots01\cdots10\cdots0\rangle_N, \]

6. the four-qubit cluster state [23]

\[ |\text{Cluster}\rangle = \frac{1}{2}(|0000\rangle + |0011\rangle + |1100\rangle - |1111\rangle). \]

We calculated the critical visibility for an increasing number 
of different settings per side. All results are presented in Table I. 
They lead to the following observations.

Observation 1. An explicit form of tight Bell inequalities 
for probabilities is known only for the following experimental 
situations: \(2 \times 2 \) [24], \(3 \times 3 \) [25,26], \(2 \times 2 \times 2 \) [25,26], 
whereby \(i \times j \) means \(i(j)\) alternative measurements on Alice’s 
(Bob’s) side. In these cases the numerical method gives the 
same critical visibility as the analytical expressions. For states 
(Nos. 1–5) (see Table I) we observe such a correspondence.

Observation 2. Local realistic correlations in the 
N-qubit experiments with two alternative measurement settings 
per side are bounded by WWWZB inequalities [6,7,10]. In this 
case, the numerical method should give better or at least the 
same results. We obtain the same results for the following states: 
GHZ(\(\pi/4\))_N (Nos. 1, 2, 13, 31, 35, 39), \(\Psi_4\) (No. 21), \(D_4^{(5)}\) 
(No. 25), Cluster_4 (No. 29), \(\Psi_6\) (No. 37), and \(D_6^{(5)}\) (No. 38). 
Stronger constraints on local realism than predicted by the 
WWWZB inequalities are observed for the following states:

1. \(|W\rangle_N\) (Nos. 17, 33, 36, 40). The corresponding critical 
   visibilities obtained by means of WWWZB inequalities 
   are equal to \(c_W^{\text{crit}} = 0.6565, \phi_W^{\text{crit}} = 0.6325\), \(c_W = 0.6202, \phi_W = 
   0.6141, \) and \(\phi_W^c = 0.6089, \) and are higher than obtained 
   by the numerical method by about 2% (for \(N = 3\)) to 208% (for 
   \(N = 7\)). The values (Nos. 5, 17, 33) were previously published 
in [27].

2. \(|\text{GHZ}(\pi/12)\rangle_N\) (No. 3), \(|\text{GHZ}(\pi/180)\rangle_N\) (No. 4). These 
   states do not violate WWWZB inequalities at all [18,28]. 
   One of the simplest examples showing the advantage of Bell 
   inequalities based on probabilities over correlation functions 
   is a three-qubit state, which is the product of the two-qubit 
   singlet state and white noise \(|\psi^-\rangle_{ab} \otimes 1_c\). The state does 
   not violate the WWWZB inequalities for three qubits, whereas 
   the numerical method detects violation of local realism and 
   gives the critical visibility equal to 0.7071. This number is 
   equivalent to the visibility, which is necessary to violate the 
   Clauser-Horne (CH) inequality by the \(|\psi^-\rangle_{ab}\) state alone.
The advantage comes from the fact that probability methods use the whole knowledge obtained from an experiment.

**Observation 3.** Explicit forms of tight correlation function Bell inequalities [29] for three qubits and three settings per side were given in [30]. The numerical method gives the same result in (No. 2). In the case of (Nos. 3, 4), the inequalities of [30] are not violated. The critical visibility for violation of the inequalities by the W state (No. 5) is equal to 0.6547 (about 2% above the visibility predicted by the numerical method).

**Observation 4.** Explicit forms of tight correlation function Bell inequalities for many qubits (N > 3) and many measurement settings (m_i > 2) are still unknown. Tight Bell inequalities were constructed for some particular cases (e.g., 2^{N-1} × 2^{N-2} × ... × 2 [31]) only. There is also the family of the correlation Bell inequalities for many qubits and an arbitrary number of settings [32]. Unfortunately, these inequalities are not tight. In this case, the numerical method gives the strongest known constraints on a local realistic description.

(a) First, let us consider the (4 × 4 × 2)-type inequality of [31]. It is violated by the GHZ(π/4), state with a critical visibility equal to 0.3536 which agrees with (No. 2). However, for the W state the inequality is violated if the visibility is higher than 0.6547 [31], whereas the numerical method reveals the critical visibility to be lower by about 4.9% (No. 7).

(b) One can also compare the numerical method with so-called geometric inequalities [32]. For instance, the critical visibility of the four-qubit GHZ state to violate the three-setting geometrical inequality \( v_{\text{geom}}^{\text{GHZ}} = 0.3421 \) is close to (but higher than) that expected by the numerical method (No. 16). However, for the four-qubit W state the three-setting geometrical inequalities are violated with a critical visibility \( v_{\text{geom}}^{\text{W}} = 0.6843 \), whereas the numerical method provides a drastically (about 28%) better result (No. 20).

**Observation 5.** One can conjecture that the critical visibility for the three-qubit W state for an arbitrary large number of settings is equal to 6/10 (No. 12).

**Observation 6.** In many cases, the critical visibility for impossibility of a local realistic description decreases with the number of settings. The highest visibility drop (19%) is observed for the five-qubit W state (Nos. 33, 34), 10% for the four-qubit W state (Nos. 17, 20), and less for W_3 (Nos. 5, 10–12), GHZ(π/4)_{4} (Nos. 13, 16), GHZ(π/4)_{5} (Nos. 31, 32), Cluster_{4} (Nos. 29, 30), \( \Psi_{4} \) (Nos. 21, 24), and D_{4}^{(2)} (Nos. 25, 28). Interestingly, for two- and three-qubit GHZ states we do not observe this effect. According to [33] it could be that the effect appears with higher numbers of measurement settings.

**Observation 7.** The minimal number of measurement settings determines a lower bound on the critical visibility. In (Nos. 5–10, 13–16, 17–20, 21–24, 25–28) the last observer has only two alternative measurement settings. Increasing the number of measurement settings at the other sides does not result in the decrease of the critical visibility below the value for three settings per each observer.

**Observation 8.** The N-qubit GHZ(π/4) state reveals the strongest nonclassical properties (the lowest critical visibility for an arbitrary number of \( N \leq 8 \)). However, one can observe that the difference between the critical visibility for the GHZ state and the W state (or the cluster state) decreases with the number of qubits. According to [27], we know that the W state leads to stronger nonclassicality than GHZ states for \( N > 10 \). Finding an example for \( N \leq 10 \) is still an open problem. Due to computer power limitations, we were not able to recover the result of Sen et al. or find another one for \( N \sim 10 \).

A. Bound entanglement

We also analyze some classes of bound entangled states, namely,
TABLE II. The critical visibilities for some bound entangled states and experimental situations (number of settings). If $v > v_{\text{crit}}$, there does not exist a local realistic model describing quantum probabilities of experimental events.

(1) the three-qubit Bennett state [34]

$$\rho_{\text{Bennett}} = \frac{1}{4} \left( I - \sum_{i=1}^{4} |\phi_i\rangle \langle \phi_i| \right) ,$$

where $|\phi_1\rangle = |01\rangle$, $|\phi_2\rangle = |10\rangle$, $|\phi_3\rangle = |+01\rangle$, $|\phi_4\rangle = |-0-\rangle$, $|\pm\rangle = (|0\rangle \pm |1\rangle) / \sqrt{2}$.

(2) the $N$-qubit Dür state [35]

$$\rho_{\text{Dür}} = \frac{1}{N+1} \left( |\phi\rangle \langle \phi| + \frac{1}{2} \sum_{k=1}^{N} (P_k + \tilde{P}_k) \right)$$

with $|\phi\rangle = \frac{1}{2^n} \left[ |0\rangle \cdots |0\rangle_N + e^{i\alpha} |1\rangle \cdots |1\rangle_N \right]$, and $P_k$ being a projector on the state $|0\rangle_1 \cdots |1\rangle_k, \cdots |0\rangle_N$ with “1” on the $k$th position ($\tilde{P}_k$ is obtained from $P_k$ after replacing “0”s by “1”s and vice versa).

(3) the generalized $N$-qubit Smolin state [36]

$$\rho_{\text{Smolin}} = \frac{1}{2^N} \left[ I^\otimes N + (-1)^{N/2} \sum_{i=1}^{3} \gamma_i^\otimes N \right],$$

where $\sigma_i$ are the Pauli matrices.

The results are presented in Table II and lead to the following observations.

Observation 9. Violation of local realism by the bound entangled Smolin state (for four and six qubits). The critical visibilities obtained by the numerical method (Nos. 43, 47) recover the results of [36]. If we go to three alternative settings per side, the critical visibility for the four-qubit Smolin state decreases (No. 44).

Observation 10. In [32, 35, 37] the problem of the violation of Bell-type inequalities by the Dür state is considered. A simple experimental situation involves seven qubits and three settings [37], six qubits and five settings [32], or eight qubits and two settings per side [35]. We only verified the case of seven qubits (No. 48). Using the numerical method, we cannot find a violation of a local realistic model for two settings per side. It suggests that the requirement of three settings is reasonable. We also partially verified the cases of four (No. 42), five (No. 45), and six (No. 46) qubits. We cannot find a local realistic model for two measurement settings per side (and three settings in the case of four and five qubits). The problem of a violation of local realism by predictions of the four- and five-qubit Dür state, and the six-qubit Dür state with the number of measurement settings less than 5 is still an open question.

As an example, in Appendix B we give a local realistic model for quantum probabilities in a Bell experiment for the four-qubit Dür state. The observers choose between two measurement settings which are optimal for the case of the GHZ state.

IV. FROM DETECTOR CLICKS TO DENSITY MATRIX

In this section we use the numerical method for experimentally observed states. To this end, we need their density matrices. Methods that are used to obtain the density matrix from the measured data are called quantum state tomography. Different ways for quantum state tomography have been developed (one of the first works was [38]; a variety of methods is summarized in [39]). From a decomposition of the density matrix into projectors, one can easily express the density matrix in terms of probabilities for detecting a certain coincidence. Relative frequencies obtained in a measurement are, however, subject to Poissonian counting statistics. Because of these uncertainties, the deduced density matrices might be unphysical, e.g., one might find negative eigenvalues. Such raw data are not useful for the numerical method and lead to the violation of local realism with visibility equal to 0, as spurious signaling-like effects may lurk in the raw data (due to experimental drifts). Fortunately, several different approaches for fitting a general physical density matrix to the measured data have been developed. There are, however, still discussions about the best method.

We apply the numerical method to the data obtained in the four-photon experiment reported in Refs. [40–42]. Spontaneous parametric down conversion in combination with linear optics was used to observe a variety of four-photon entangled states:

$$|\psi(\gamma)\rangle = \frac{1}{2} \gamma ((|0\rangle + |10\rangle) \otimes 2$$

$$+ \sqrt{1 - \gamma^2} (((|00\rangle + |11\rangle)) \otimes 2). \quad (9)$$

We select three of these states, namely, $|\psi(0)\rangle \equiv |\text{GHZ}(\pi/4)\rangle_4$, $|\psi(1/3)\rangle \equiv |\Psi_4\rangle$, and $|\psi(2/3)\rangle \equiv |D_4^{(2)}\rangle$. 

012118-5
Moreover, two further states, namely, \(|\text{GHZ}(\pi/4)\rangle_2\) and \(|W\rangle_3\) are obtained from the state \(|\psi(2/3)\rangle\) after projective measurements. The experimental states were deduced from a full quantum state tomography with a maximum-likelihood estimation [43] of the most likely density matrix to have led to the observed data.

The STEAM-ROLLER was used to determine the critical parameter \(v^{\text{crit}}_{\text{expt}}\) for the tomographically reconstructed states (see Table III). If \(v^{\text{crit}}_{\text{expt}} < 1\), the experiment cannot be described by any local realistic model. The critical parameters \(v^{\text{crit}}_{\text{expt}}\) can be compared with theoretical ones \(v^{\text{theor}}_{\text{crit}}\) obtained for ideal states. The critical visibility in the experiment is always larger than the theoretical one. This is due to the nonideal preparation of the states in the experiment, which essentially reduces the nonclassical correlations. Further, the ratios \(v^{\text{theor}}_{\text{crit}} / v^{\text{expt}}_{\text{crit}}\) are slightly greater than the experimental fidelity of a given state, e.g., for the Dicke state (No. 57) \(v^{\text{theor}}_{\text{crit}} / v^{\text{expt}}_{\text{crit}} = 0.86\), whereas \(F^\text{Dicke}_{\text{expt}} = 0.83\). This can be explained by the fact that the noise observed in the experiment contains nonclassical correlations [44,45].

## V. CLOSING REMARKS

In this paper we used linear programming as a tool to study the nonclassicality of quantum states. The detailed comparison of a number of multipartite entangled states demonstrates the power of this method even for modest computer equipment. Most of the conclusions were spelled out in the earlier sections. Here we want to stress that the overall message of the obtained data is that with more settings per observer, one gets stronger violations of local realism. The strength of violation also increases with the number of qubits (see Fig. 1).

We would like to draw the attention of the reader to the peculiarity of three-qubit GHZ states. It is well known that the threshold visibility for the GHZ correlations to violate the Mermin three-qubit inequality is 0.5. This inequality only considers highest order correlation functions. This threshold is very stubborn. As outlined previously, in our numerical approach we used not the correlation functions, but the full set of probabilities, for events of all orders. Still, even if one increases the number of settings from two per observer to five, the stubborn threshold stays put at 0.5, see also [46].

![FIG. 1.](image_url) The bars represent, for several families of quantum states, the critical visibilities, which are necessary to falsify a local realistic description in two setting experiments. The additional line in some cases corresponds to the value of the critical visibility in a three-setting experiment.

An interesting extension of the phenomenon are four-qubit GHZ states: if one increases the number of settings from two to four for three observers only, with the last one always using two settings, the threshold visibility is 0.3536 for all such cases. The exact value seems to be \(\frac{1}{\sqrt{2}}\), as such is the analytic value for standard Bell inequalities (in the two settings per observer scenario). However, in the \(3 \times 3 \times 3\) case, suddenly the critical visibility drops to 0.3408. All this points to some so far unexplained resistance of three-particle correlations, even within a four-particle GHZ state, to reveal more nonclassicality with an increasing number of settings. It should be an exciting task to find a reason for that behavior.

The collaboration is a part of a DAAD/MNiSW program. M.˙Z. thanks Nicolas Gisin for discussions on the problem studied in Sec. IV.

## APPENDIX A: LOCAL REALISTIC MODEL FOR THE NOISY \(|\text{GHZ}(\pi/4)\rangle_2\) STATE

The quantum probability function for the GHZ(\(\pi/4\))\(_2\) state has the following form:

\[
P_{QM}(r_a, r_b; \theta_a, \phi_a; \theta_b, \phi_b) = \cos (r_a \pi/4 + \theta_a) \cos (r_b \pi/4 + \theta_b) + \sin (r_a \pi/4 + \theta_a) \sin (r_b \pi/4 + \theta_b) \cos (\phi_a + \phi_b).
\]

(A1)
Let us choose some arbitrary set of measurement angles: 
\( \theta^i = 0, \phi^1 = 0; \phi^2 = \pi/2; \phi^3 = \pi/4; \phi^4 = 3\pi/4 \) and put (A1) to (1). Then we get the set of constraints under which the visibility function \( v \) should be maximized:

\[
\begin{align*}
\ p_0 + p_1 + p_5 + p_4 &= q_{-}, \\
\ p_2 + p_3 + p_7 + p_6 &= q_{+}, \\
\ p_4 + p_5 + p_{13} + p_{12} &= q_{-}, \\
\ p_6 + p_7 + p_{14} + p_{15} &= q_{+},
\end{align*}
\]

(A2)

with \( q_{\pm} = \left(1 \pm \sqrt{2}/4\right)/p_i \leq 1 \), and \( \sum_i p_i = 1 \). For such a problem the numerical procedure gives the highest possible visibility \( v_{\text{crit}} = 0.707107 \), for which a local realistic model of (A1) exists. For such a value of \( v = v_{\text{crit}} \), the local realistic model has the following form:

\[
\begin{align*}
\ p_0 &= 0, & \ p_1 &= 1/8, & \ p_2 &= 0, & \ p_3 &= 1/8, \\
\ p_4 &= 1/8, & \ p_5 &= 1/8, & \ p_6 &= 0, & \ p_7 &= 0, \\
\ p_8 &= 0, & \ p_9 &= 0, & \ p_{10} &= 1/8, & \ p_{11} &= 1/8, \\
\ p_{12} &= 1/8, & \ p_{13} &= 0, & \ p_{14} &= 1/8, & \ p_{15} &= 0.
\end{align*}
\]

Note that in this example, the measurement was chosen arbitrarily (but in an optimal way). In a standard procedure, there is an additional optimization over measurement angles.

APPENDIX B: LOCAL REALISTIC MODEL FOR A BOUND ENTANGLE STATE

The local realistic model for the quantum probabilities for the four-qubit Dür state is presented. The measurement angles are chosen in the optimal way for the GHZ\((\pi/4)\) state, namely, \( \theta^i = 0(i = 1,2,3,4; j = 1,2), \phi^1 = 0, \phi^2 = \pi/2, \phi^3 = \pi/4, \phi^4 = 3\pi/4, \phi^5 = 3\pi/4 \). Any other choice of measurements does not have an impact for violation of local realism. The model has the following form:

(i) \( p_0 = p_{15} = p_{21} = p_{26} = p_{38} = p_{41} = p_{51} = p_{60} = p_{67} = p_{76} = p_{112} = p_{127} = p_{150} = p_{153} = p_{165} = p_{170} = 0.0404029, \)

(ii) \( p_{88} = p_{90} = p_{102} = p_{105} = p_{128} = p_{143} = p_{279} = p_{188} = p_{195} = p_{200} = p_{234} = p_{217} = p_{229} = p_{235} = p_{240} = p_{248} = p_{255} = 0.00379126, \)

(iii) \( p_{216} = p_{219} = p_{226} = p_{238} = p_{245} = 0.0366117, \)

(iv) \( p_{216} = p_{233} = 0.0328204. \)

All other probabilities vanish.
[46] Unfortunately, at the moment we cannot extend our investigations to more settings than five. This is because of the memory requirements of the program and speed of the machine. Further, we cannot be 100% certain that the algorithm reaches the global minimum. Still, the program is constructed in such a way that it never gives too low values for $v_{\text{crit}}$. Thus, we are always on the safe side with our claims of nonclassicality.
